USE OF THE TENSOR PRODUCT FOR NUMERICAL WEATHER PREDICTION BY THE FINITE ELEMENT METHOD - PART 1.

Introduction

In Ref. 1 Hinsman has developed a Finite Element (FE) program for Numerical Weather Prediction applications. The grid employed is rectangular with nodes at the intersections of north-south and east-west lines. It was shown by Staniforth and Mitchell (Ref. 2) that the coefficient matrices for such a grid could be expressed as tensor products. these products the factors are matrices which depend solely on grid spacing in the two orthogonal directions. report deals with the coefficient matrix called the "mass" (In Refs. 3 and 4 applications of matrix in FE parlance. the tensor product resolution to the FE "stiffness" matrix are considered.) The theory which underlies the economical computational scheme based on the mass matrix resolution is first presented. Next, the number of floating point operations and the number of storage locations needed for the coefficient matrix of this scheme are compared with those required by other better-known algorithms. A set of FORTRAN subroutines for implementing the tensor product scheme (TENSOR) is given in Appendix B.

Theory

Consider the grid shown in Fig. 1. There are n spaces

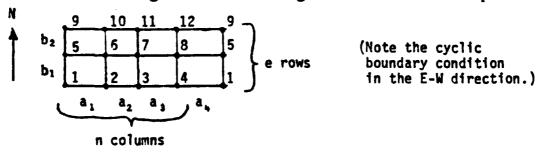

Fig. 1. Node numbering and spacing.

along each of e grid lines in the east-west direction. Node numbering is from west to east along successive grid lines,

beginning in the southwest corner. There is a cyclic boundary condition in the east-west direction so that the node number appearing at the beginning of each horizontal row is repeated at the end. Spacings of the horizontal and the vertical grid lines are not necessarily uniform.

The computational problem addressed here is the solution of the equation

$$Mw = v$$
 <1>

where M (t e "mass" matrix) is a square, symmetric matrix of size ne and w and v are column vectors of height ne. M and v are input quantities and w is sought. The tensor product representation of M is

$$M = MB * MA$$
 <2>

where MB is a square, symmetric, tridiagonal matrix of size e and MA is also square, symmetric and of size n. MA is tridiagonal except for nonzero elements in upper right and lower left corners. MB depends solely on the north-south node spacing b and MA depends upon the east-west node spacing a. The asterisk (*) denotes the tensor product. Explicit expressions for matrices MA, MB, and the tensor product are given in Appendix A.

Let MB be represented as (e = 3)

TO THE PROPERTY OF THE PROPERT

$$MB = \begin{bmatrix} mb_{11} & mb_{12} & 0 \\ mb_{21} & mb_{22} & mb_{23} \\ 0 & mb_{32} & mb_{33} \end{bmatrix}$$
 <3>

If we partition w and v into e n x 1 subvectors so that

$$\mathbf{w} = \begin{bmatrix} \mathbf{w}_{\mathbf{I}} \\ \mathbf{w}_{\mathbf{I}\mathbf{I}} \\ \mathbf{w}_{\mathbf{I}\mathbf{I}\mathbf{I}} \end{bmatrix} \qquad \mathbf{v} = \begin{bmatrix} \mathbf{v}_{\mathbf{I}} \\ \mathbf{v}_{\mathbf{I}\mathbf{I}} \\ \mathbf{v}_{\mathbf{I}\mathbf{I}\mathbf{I}} \end{bmatrix}$$

we may use <2>, <3> and <4> to rewrite <1> as

Define W = <W_I W_{II} W_{III}>

and $V = \langle V_T | V_{TTT} \rangle$

It is easy to verify that the equations <5> are equivalent to

MA W MB = V <7>

<6>

Solution of <7> can be accomplished by standard Gaussian elimination procedures. Specifically, the following steps are required.

- LDLT factoring of MA (n x n).
 Forward reduction and back-substitution for e right-
- hand side vectors.

 (3) LDLT factoring of MB (e x e).

 (4) Forward reduction and back-substitution for n right-hand side vectors.

This entire process is economical of both storage and arithmetic operations because of the tridiagonal structure of MA and MB.

Boundary Conditions

The cyclic boundary condition is implemented by repeating the node numbers of the western boundary on the eastern boundary as shown in Fig. 1. As already noted, this accounts for nonzero entries in the upper right-hand and lower left-hand corners of MA.

It is sometimes required to impose a Dirichlet boundary condition on the southern and northern boundaries of the region. Specifically, the subvectors w and w of the solution vector w are prescribed. To implement this boundary condition the following modifications to the standard solution procedure are required.

In the n x e matrix V on the right-hand side of <7> the first and last columns are replaced by the prescribed boundary values of w, i.e., put $v_I = w_I$ and $v_e = w_e$. Let X = W MB and solve the system

$$MA X = V < 8 >$$

processing successive columns of V in standard fashion, but omitting the first and last columns. The reduced problem

now takes the form W MB = X and the first and last columns of X are \mathbf{w}_{I} and \mathbf{w}_{e} , respectively. Transposing both sides of this equation gives

$$MB WT = XT < 9$$

where WT and XT are the respective transposes of W and X (recall that MB is symmetric and is thus not altered on transposition). Since the first and last rows of WT are known, the corresponding scalar equations are not needed. Accordingly, we form MBl by deleting the first and last rows of MB. We also reduce XT to XTl by omitting the first and last rows. This leaves the result

$$MB1 WT = XT1 <10>$$

or, in extenso, this takes the form (for n = 3, e = 5)

$$\begin{bmatrix} mb_{21} & mb_{22} & mb_{23} & 0 & 0 \\ 0 & mb_{32} & mb_{33} & mb_{34} & 0 \\ 0 & 0 & mb_{43} & mb_{44} & mb_{45} \end{bmatrix} \begin{bmatrix} k & k & k \\ u & u & u \\ u & u & u \\ k & k & k \end{bmatrix}$$

(In WT and XT1 the elements denoted by "k" are known and those denoted by "u" are unknown.) This equation may be put in standard form by first altering the first row of XT1 by subtracting mb₂₁ times the corresponding entries in the first row of WT and altering the last row of XT1 by subtracting mb₄₅ times the corresponding entries in the last row of WT. Calling the new right hand side XT2 and forming MB2 from MB1 by discarding the first and last columns and forming WT1 by discarding the first and last rows of WT, the result is

CONTROL CONTROL AND MARKET AND MARKET CONTROL CONTROL

$$MB2 WT1 = XT2$$
 <11>

Solution of <11> is carried out by LDLT factoring of MB2, followed by forward reduction and back substitution.

Floating Point Operations and Matrix Storage Requirements

Presented here is a comparison of floating point operation counts and matrix storage requirements for the tensor product scheme and three widely-used solution algorithms for

solving <7> or its equivalent <1>. Three of the schemes take advantage of symmetry of the coefficient matrices and store only elements on or above the principal diagonal. One of these, the "band solver" (BAND), places these elements in a rectangular matrix ne x r, where r is the maximum row length of the upper triangle of M. The "sky-line solver" (SKY) further economizes by storing only that part of the upper triangle beginning at the diagonal and extending to the topmost nonzero element of each column. These subvectors are assembled into a single vector. This requires an additional integer address vector of length ne + 1. The remaining algorithm, "successive over-relaxation" (SOR), is iterative rather than direct.

In most applications of the direct solvers the number of floating point operations required to factor the coefficient matrix into LDLT form is much greater than those required to complete the process of finding a single solution vector w corresponding to a given right-hand side vector v (forward reduction and back-substitution). In the present application, however, the latter solution process must be carried out 17 times for each time step, so that the LDLT factoring makes a negligible contribution to the total computational expenditure. Accordingly, the operations required for factoring are not included in the tabulation below.

In the following table the results given for the number of floating point operations are given in terms of the grid parameters n and e (defined in Fig. 1). One multiplication (or one division) plus one addition (or one subtraction) is counted as one operation. Exact results for these operation counts would take the form of a polynomial in n and e. Only the highest degree terms are given in the table. Since it is not possible to predict the number of iterations per solution when using SOR, the operation count given for that algorithm is for a single iteration. Also, since the number of storage locations required for SOR coefficient matrices is highly grid-dependent, no such entry is given for SOR.

TABLE I. Operation Counts and Storage Requirements.

| Algorithm | Number of Operations per Solution | | Number of Storage Locations for Coefficient Matrices | |
|-----------|-----------------------------------|-----|--|-----|
| SOR | 10 en | (1) | | (2) |
| SKY | 2 en² | | en² | |
| BAND | 4 en² | | 2 en² | |
| TENSOR | 8 en | | 3 n + 4 e | |

Notes: 1. Number of operations per iteration.
2. Number of storage locations is grid-dependent.

Conclusion

Close comparison of operation counts and storage requirements leads to the conclusion that the TENSOR algorithm is clearly superior to the SKY and BAND algorithms. The comparison with SOR is not as clear-cut. Considering, however, that the operation count for SOR is for only one iteration, there really seems to be little doubt that TENSOR is the method of choice.

APPENDIX A MATRICES MA, MB, AND THE TENSOR PRODUCT

Symbols a; and b; which appear in MA and MB are defined in Fig. 1.

$$MA = \frac{1}{6} \begin{bmatrix} 2(a_1+a_1) & a_1 & 0 & a_4 \\ a_1 & 2(a_1+a_2) & a_2 & 0 \\ 0 & a_2 & 2(a_2+a_3) & a_3 \\ a_4 & 0 & a_3 & 2(a_3+a_4) \end{bmatrix}$$

$$MB = \frac{1}{6} \begin{bmatrix} 2 b_1 & b_1 & 0 \\ b_1 & 2(b_1 + b_2) & b_2 \\ 0 & b_2 & 2 b_2 \end{bmatrix}$$

The tensor product of matrices C and D may be represented in block partition form as

$$C * D = \begin{bmatrix} c_{11} D & c_{12} D & c_{13} D \\ c_{21} D & c_{22} D & c_{23} D \\ c_{31} D & c_{32} D & c_{33} D \end{bmatrix}$$

where the c_{ij} are the elements of C. Note that, if C and D have dimensions r x s and t x u, respectively, the tensor product has dimensions rt x su.

APPENDIX B FORTRAN PROGRAM LISTINGS

FORTRAN programs for the implementation of TENSOR are listed here. They appear in the form of subroutines AMTRX2, FACTOR, BACKA, and BACKB within the test program GAUSS3. (The subroutines FACTOR, BACKA, and BACKB are adapted from subroutine COLSOL of Ref. 5.) Also included are GOG3, an Exec used to execute GAUSS2 - a dimensioned version of GAUSS3, and CDIM, an Xedit program used to enter the dimensions.

        THIS SUBROUTINE FORMS THE MASS MATRIX IN THE FORM OF A TENSOR PRODUCT OF THE GB MATRIX AND THE GA MATRIX.

THE FIRST OF THESE IS NLAT + 1 BY NLAT + 1 SYMMETRIC, AND TRIDIAGONAL. THE SECOND IS NLONG BY NLONG, SYMMETRIC, AND TRIDIAGONAL EXCEPT FOR SINGLE ELEMENTS IN UPPER RIGHT HAND AND LOWER LEFT HAND CORNERS. GB IS STORED IN SKYLINE VECTOR FORM (UPPER TRIANGLE WITH SPACE FOR FILL-IN) AS GB1 AND GB2. THE LATTER VERSION IMPOSES A DIRICHLET BOUNDARY CONDITION ON THE NORTH AND SOUTH BOUNDARIES. GA IS ALSO STORED IN SKYLINE VECTOR FORM. INTEGER ADDRESS VECTORS MB AND MA ARE ALSO GENERATED.
              INTEGER ADDRESS VECTORS MB AND MA ARE ALSO GENERATED.
